The effect of the cutting fluid with zinc aspartate on the quality of the workpiece surface layer is reported. Until now, zinc aspartate has been used primarily in medicine and pharmacology. This paper compares the ecological cutting fluid containing zinc aspartate with a classic mineral oil-based coolant. Toxicity tests and a controlled process of tool wear during face turning were performed. Test results indicate that the use of zinc aspartate-based cutting fluids contributes to the reduction of the material roughness parameter values up to 35%, benefitting the final quality of the workpiece.

**Keywords:** ecological cutting fluid, zinc aspartate, tool wear, surface topography, microbiological tests.

**1. Introduction**

Machining is the most commonly used method of manufacturing components and parts in virtually all production technologies [18, 20]. Machining operations use cutting fluids [2, 23] to cool, lubricate and improve the surface condition of the machined part [22], to transport chips from the machining zone [3] and temporarily protect the product against corrosion [6, 21]. In order to fulfil their tasks, cutting fluids must have a special chemical composition, which cannot adversely affect people or the environment [2, 6, 24]. The most widely used cutting fluids are based on water or oil. Despite the obvious advantages, including low cost, mineral oil-based fluids are toxic for the environment and their degradation processes are difficult to control [18, 20]. In addition, friction modifiers, extreme pressure (EP) and anti-wear (AW) additives, corrosion inhibitors, antioxidants, etc. [1, 3, 10, 16] used in the fluids may add to their harmful effects.

Yadav et al. [21] examined the impact of EP and AW additives in new and used engine oils class SAE 15W40 and SAE 20W50 on the wear of the test balls. The tests were carried out on a Ducom TR-30L four-ball tester at a temperature of 75°C, under a load of 392 N and at a constant speed of 1250 rpm. The results indicated that the wear scar diameter after tests increased gradually with increasing oil use time. It was found that the effect of EP and AW additives was primarily determined by the engine oil operating conditions.

Maruda et al. [8] studied the impact of EP and AW additives on the topography of steel surfaces during MQCL turning with various coolants at varying flow rates. The results showed that the addition of phosphate ester-based additives to the active medium resulted in the formation of a tribofilm at the tool-chip interface, which reduced friction. The lubrication method using a minimum amount of coolant with EP/AW substances improved surface topography parameters.

In another article, Maruda et al. [10] compared dry machining and cooling with compressed air, emulsion mist, emulsion mist + Crodafos O4A-LQ-(MH) and emulsion mist + Crodafos EHA-LQ-(MH). They found that cooling with emulsion mist and modifiers can provide an 80% reduction of roughness parameters.

Maruda et al. [8] reported the results from introducing the additives in the emulsion mist first on the processed surface and then to the contact zone of the friction pair. The quality of the machined stainless steel surface improved as a result of reduced roughness, and phosphate ester-based additives used in the emulsion mist intensified this effect. The phosphate-based additives remained on the machined surface even after 30 minutes of machining under high loads, temporarily lowering the friction coefficient and temperature in the interface zone.

Lubricants based on vegetable oil are introduced to the market for their biodegradability and non-toxicity. They are a potential lubricant preparation alternative that does not use petroleum derivatives [15, 17]. Much work has been devoted to research on cutting fluids based on vegetable oils.

Ozcelik et al. [14] tested coolants based on sunflower and rapeseed oil with an EP additive at 8% and 12%. The metalworking fluid containing rapeseed oil provided a better surface quality of the workpiece than that based on sunflower oil by more than 11% and 4%, respectively. Kumar et al. [5] studied coconut oil coolant with EP additives. They showed that coconut oil reduced the feed force by 31%, the pressure force by 28%, the cutting force by 20%, the cutting tool temperature by 7% and the wear of the tool face by 34% compared to other machining fluids.

In turn, Zhang et al. [24, 25] tested soybean coolants, which were compared to petroleum-based machining fluids and dry machining. They showed that the soy-based coolant worked similarly to the petroleum-based fluid. At the same time, they obtained much better surface roughness and less tool wear, compared with coolant-free machining.

Trajano et al. [19] performed tribological tests of sunflower and soybean oils containing CuO additives and ZnO nanoparticles. In the case of soybean nanofluids with CuO and ZnO concentrations of 0.5 wt.%, the friction coefficient decreased by 11% and 18% respectively. However, for the sunflower oil with the same filler fraction, the coefficient of friction decreased for CuO and ZnO by 22% and 20%, respectively.

The literature review above shows that there are large gaps in coolant research. To date, no studies have been conducted to determine the effect of zinc aspartate as a biodegradable modifying additive for cutting fluids. Bibliometric analysis indicates the use of zinc aspartate in cutting fluids in the last 15 years. This paper presents the results obtained during the machining operation with the use of a non-toxic cutting fluid containing zinc aspartate. Its impact on selected factors and surface quality of the machined workpiece was also determined.

2. Materials

2.1. Metalworking fluids

The fluid used in the tests was an eco-friendly, demineralized water (DEMI) based cutting fluid with 5% zinc aspartate and, among others:

- alkanolamine borate;
- a biodegradable oligomer based on poly(aspartic acid) (PASA);
- demineralized water.

Zinc polyaspartates ensure the fluid biostability. Physical and chemical properties of the cutting fluid used are summarized in Table 1.

A zinc aspartate-containing coolant was compared to a commercial cutting fluid based on mineral oil and containing ethoxylated aliphatic alcohols with chain lengths C16-18, boric acid, dicyclohexylamine, 3-iodo-2-propynyl butylcarbamate, and 1,2-benzisothiazol-3 (2H)-one. It is used for general to heavy machining of aluminium, steel, cast iron, non-ferrous metals, aluminium alloys, brass and copper. The fluid contributes to the good quality of machined surfaces. The basic parameters of the fluid are compiled in Table 2.

2.2. Machined materials and tools

A tool made of HS6-5-2C steel was used for turning the front faces on the workpiece. This steel is characterized by very good ductility, impact strength and abrasion resistance. It is designed for high speeds on CNC machines, high speed tool steel is still an economical alternative, given the price and easy sharpening. Steels obtained by sintering high-speed steel powders are increasingly used for tools, whose blades are coated with complex coatings dedicated to specific applications.

The workpiece was a 38 mm diameter roller made of C45 steel, which is a non-alloy, medium carbon steel for quenching and tempering, difficult to weld, easy to machine, with the chemical composition as in Table 4. Products made of C45 can be surface hardened to 50 ÷ 60 HRC.

3. Methods

A FTIR Spectrum Two infrared spectrometer with the Perkin Elmer ATR adapter was used to test the thermo-oxidative kinetics of operating fluids. Oligomer samples were measured as pure and after model tribological tests. The following analytical parameters were used during spectral tests:
For the microbiological assessment of fluid toxicity, a special Microbiology Cult Dip Combi kit was used to determine the presence of microorganisms. It consisted of containers with attached test plates covered with appropriate media. One side of the test plates was lighter and was used to detect the presence of bacteria, and the other side was darker to detect the presence of yeast and fungi. All parts of the test kit were sterile. Toxicity tests according as per instructions [12] were applied to the zinc aspartate-containing fluid and the conventional mineral oil-based coolant. The samples were checked first after 48 hours, then after 96 hours and finally after 7 days. At 7 days the samples were subjected to organoleptic assessment and compared with microorganism colony standards (Fig. 1).

Replaceable cutting tools were used - insert tool bits with a square cross-section 10 mm x 10 mm, held in a bit socket. The inserts were made of high speed steel HS6-5-2C. The geometry parameters were as follows:

- major cutting edge angle \( K_r = 36.6^\circ \) in the reference plane \( P_n \),
- minor cutting edge angle \( K_r' = 53.4^\circ \),
- positive rake angle \( \gamma = 5.3^\circ \),
- tool included angle \( \varepsilon_r = 90^\circ \),
- cutting edge inclination angle \( \lambda_s = 7^\circ \) in the cutting edge plane \( P_s \),
- clearance angle \( \alpha = 5.3^\circ \),
- rake angle \( \gamma = 7^\circ \),
- wedge angle \( \beta = 77.7^\circ \),
- nose radius \( r_n = 0.04 \text{ mm} \).

The workpiece material was a C45 steel roller with a diameter of 38 mm. During turning, conventional flood cooling was applied to the tool rake face. The view and diagram of the coolant supply and discharge system is shown in Figure 2.
Ten stages of face turning were performed. The first stage consisted of 10 passes, and 10 more passes were added in each subsequent stage (Fig. 3). After each stage, a thin piece – a “slice” of the workpiece – was cut off and the cutting tool was replaced.

The aim of the study was to assess the basic operating characteristics of the new, zinc aspartate-based cutting fluid and the wear of the cutter during face turning.

A JEOL JSM-7100F scanning electron microscope was used to examine the surface topography of workpieces and cutting tools. The EDS microanalyzer enabled the identification of chemical elements on the surface of cutting tools at the built-up edge after the 10th turning cycle with coolants.

Geometry of the workpiece after turning was imaged using a DCM8 confocal microscope from Leica. In addition, the SX80 stereoscopic inspection microscope was used to observe the wear of the cutting tools after machining.

4. Results

Figure 4 compiles FTIR spectra which show a clear intensification of two bands with increasing load and friction path. The low intensity signals with a peak maximum at about 1394 and 1066 cm⁻¹ correspond to C-O (COH) stretching vibrations and indicate the initiation of coolant degradation processes and the formation of a carboxyl group. Observations of the cutting fluid containing zinc aspartate after tribological tests reveal a change in its colour. With increasing load and friction path, the colour becomes darker, from light yellow to brown.

The cutting fluid can be regenerated by supplementing the basic component - zinc aspartate and controlling other operating parameters.

Toxicity of the zinc aspartate-based coolant and, for comparison, of the mineral oil-based fluid was evaluated using the Microbiology Cult Dip Combi kit. Two samples of each fluid were used in the tests. Observations began after 7 days (Figs. 5 and 6).

The cutting fluid containing zinc aspartate was found to be non-toxic. No colonies of bacteria (Fig. 5a), yeast or mould (Fig. 6a) were formed. However, on one of the slides earlier immersed in the mineral oil-based coolant several spots on the bacterial count side were observed (Fig. 5b). According to the guidelines [12], these spots indicate a minor infection. Considering the results obtained, the zinc aspartate coolant turned out to be better than the mineral oil-based coolant.

Using the inspection microscope software, wear measurements on the flank face were carried out in accordance with the standard [13], as shown in Fig. 7.

The charts above show that the average $VB_b$ and maximum $VB_b$ max values of the wear bandwidth were 0.03 mm and 0.05 mm respectively.
tively after the treatment with the coolant containing zinc aspartate. The tool wear parameters after turning with the coolant containing mineral oil were higher.

Figure 8 presents SEM images of cutting blades wear after dry machining and machining with the use of coolants, and the results of chemical composition analysed in micro-areas using the EDS method. After the final 10th turning test with coolants, built-ups formed in the place of wear on the cutting tools. Chemical composition of this excessive material was examined by scanning electron microscopy.

After turning with the zinc aspartate containing cutting fluid, a concentration of zinc atoms was recorded in addition to the elements included in the tool. This indicates that a thin surface layer of zinc compounds with anti-wear properties was formed as a result of tribochemical processes that occur mainly between improvers, contained mainly in lubricants, and friction surfaces. The speed and type of chemical reactions depend on the operating conditions of the friction node. The surface reaction layer produced in this way changes the working conditions of the friction pairs, which in turn leads to further tribochemical reactions. This surface layer reduces friction and extends the service life of friction pairs [16].

A comparison of the contour maps, isometric views and primary profiles reveals an even distribution of vertices [7] almost every 1 mm (feed: 0.098 mm) in both cases. The lowest elevations of approx. 16 µm and the shallow cavities of approx. 15 µm were formed on the workpiece after turning with the fluid containing zinc aspartate. In contrast, the highest elevations/peaks and depressions/valleys of about 20 µm were recorded after turning with the coolant containing mineral oil.

Table 6 shows the parameters of the geometric structure of machined surfaces formed after turning with the use of zinc aspartate and mineral oil cutting fluids.

The values of surface roughness parameters of machined elements after the turning process with zinc aspartate containing coolant are lower than those for the mineral oil coolant. This indicates that the cutting fluid improves the surface quality of the workpiece.
4. Conclusion

The conclusions based on the test results are the following:
1. The cutting fluid with zinc aspartate used in the turning process reduced the wear of elements of the tribological system by forming layers containing zinc compounds with good anti-wear properties.
2. The workpiece subjected to turning with the zinc aspartate containing fluid had the lowest elevations and shallowest recesses after the process.
3. Surface morphology in the turning process depends on the direction of movement and size of the feed.
4. The non-toxic coolant with zinc aspartate was undergoing transformation as a result of the reactions dependent on the operating conditions.
5. The cutting fluid containing zinc aspartate does not show any toxic properties and can be subjected to simple regeneration.
6. Due to its good ecological properties, the tested cutting fluid with zinc aspartate can be used during operation on conventional lathes, where the operator’s direct contact with the coolant is greater than on numerically controlled lathes.
7. The cutting fluid with zinc aspartate provided better technological quality of the surface layer of machined elements and extended the life of high speed steel tools compared to classic coolants. The surface roughness values after the use of zinc aspartate cutting fluid were lower (by 22% for $S_a$, by 25% for $S_q$, by half for $S_p$, by 11% for $S_v$, by 35% for $S_z$, more than 2 times for $S_{sk}$, and by 17% for $S_{ku}$).
